NELHA MARINE BIOTA MONITORING PROGRAM

November 2010

EXECUTIVE SUMMARY

The Natural Energy Laboratory of Hawaii Authority (NELHA) and the Hawaii Ocean Science and Technology (HOST) Park are located at Keahole Point, North Kona, Hawaii. These State of Hawaii facilities share infrastructure for the delivery of water from a variety of sources, including wells and offshore pipelines; water is disposed of primarily via discharge into open trenches in the shore side lava. In order to fulfill the requirements of permits to discharge, NELHA/HOST established the Comprehensive Environmental Monitoring Program (CEMP; G. K. & Associates, 1989). The objectives of the CEMP are to protect the environmental resources of the Keahole Point area and to provide the information necessary to comply with the permit requirements of county, state and federal agencies.

The CEMP is divided into two components: the water quality monitoring component and the marine resources component. The water quality monitoring component is being performed by staff of NELHA, and technical reports from that effort are prepared periodically. The marine biota monitoring component has been performed under contract by technical consultants. David A. Ziemann, Ph.D. is the current recipient of the contract award. Monitoring addresses three marine biotic components: anchialine ponds, nearshore benthic communities and nearshore fish communities. This report presents the results of monitoring surveys conducted in November 2010.

The ponds at NELHA exhibit both groups with high abundance of *Halocaridina rubra* (a unique brackish water shrimp locally known as opae ula), and others where *H. rubra* is excluded by the presence of exotic fishes. In the past, exotic fish had been present in all of the northern ponds and about one-third of the southern ponds. Some modifications to several of the northern ponds were made between November 2005 and July 2006. *Ruppia* has been removed from Ponds N2, N3 and N4 and replanted in the deeper portions of N5. Also, poecillids were apparently successfully removed, at least temporarily, from the northern ponds; their presence was noted in our January 2007 survey, but none were observed during the October 2008 survey, and they have remained absent through the present survey. As an apparent consequence of the removal of exotic fishes, *Halocaridina rubra* were seen in all the northern ponds in abundance, along with *Metabataeus lohena*. A large pond was dug in the sandy back-beach near the northern ponds sometime in 2008. Until the present survey, the new pond had been barren of anchialine organisms. During this survey, significant numbers of *Halocaridina rubra* were observed in this new pond. Whether they reached the pond naturally or were introduced manually is not known. These observations suggest that selective removal of exotic fish can be accomplished, and that the native anchialine pond crustaceans can return to ponds from which they were excluded; however, these changes may be short-lived if constant maintenance is not undertaken.

None of the ponds exhibit any conditions which might be attributable to anthropogenic inputs of material to the ponds. Water clarity remains high, and macroalgal growth is minimal even in ponds containing exotic fish. There is no evidence of any long term changes attributable to facility operations on the anchialine ponds at NELHA.

Total coral cover, *Porites lobata* cover, *Pocillopora meandrina* cover and coral species diversity have been monitored over the period from May 1992 to November 2010. The data suggest that there may have been systematic differences in monitoring protocols between contractors. Independent of these differences, the data suggest that total coral cover and cover of individual species have gradually increased over the period May 1992 to November 2010. This increase is the result of the continued growth of existing corals, the settlement and growth of new corals, or a combination of the two processes. No other significant changes in benthic communities have been observed. There is no evidence that the operational activities at NELHA have had any impact on the benthic communities in the region.

The fish community in the NELHA region has remained relatively constant over a period of nineteen years and through several significant storm events. Analysis of variance of number of species, number of individuals and biomass over the period from May 1992 to November 2010 showed no significant change with time. There is no evidence that the NELHA operations have resulted in any significant changes to the fish communities in the region.

NELHA ANCHIALINE POND MONITORING PROGRAM

November 2010

INTRODUCTION

Anchialine ponds are brackish water bodies separated from the ocean but responding to the rise and fall of the tides. In Hawaii, anchialine ponds are found predominantly on low lying coastal lava where depressions in the lava extend below the water table. Anchialine ponds are inhabited by a community of unique organisms adapted for life in these conditions. The predominant species include several crustaceans, mollusks and other invertebrates. Because these unique ecosystems are found at the distal edge of the groundwater lens, they are potentially sensitive indicators of pollution to groundwater and the marine environment by terrestrial activities and processes.

The anchialine ponds at NELHA were first surveyed by Maciolek and Brock (1974). They observed pond systems which were relatively pristine, with typical communities of aquatic plants and animals. Subsequent surveys by OI Consultants, Inc. (Ziemann, 1985) and G.K. & Associates (G.K. & Assoc., 1986) found essentially unchanged conditions, with generally the same flora and fauna. Notably absent in all these surveys were exotic fish.

Since 1989, the anchialine ponds at NELHA have been surveyed as part of the CEMP. Between 1989 and the present, 33 surveys of the ponds have been completed. The results of the first 12 surveys (through June 1995) are summarized in Brock, 1995; for November 1995 through May 1997 in Oceanic Institute, 1997; for December 1997 through May 2002 in Brock 2002; for July 2005 – January 2007 in Oceanic Institute 2007; for December 2007 and August 2008 in Brock 2008; for October 2008, May 2009 and March 2010 in Ziemann 2008, 2009, 2010. Results of the pond monitoring survey conducted in November 2010 are presented below.

METHODS

Anchialine ponds are located in two groups on the NELHA site (Figure 1): Prior to 2008, five ponds were located near the shoreline to the north of NELHA (Figure 2 upper). Sometime in 2008 an additional pond was dug in the sandy back-beach area adjacent to Pond N1; this pond has been labeled N6. Nine ponds are located to the south, inland of the NELHA access road (Figure 2 lower). A survey of the general conditions and biota within the ponds was conducted for this project on November 14, 2010 in morning hours on a high (1+ foot) tide. At each pond, water temperature was determined with a mercury thermometer and salinity was determined with a hand-held refractometer calibrated against distilled water. From one to four 0.1 m² quadrats were placed in each pond, in areas of different substrate, if possible. After five minutes, the number of organisms within each quadrat was counted and recorded. The presence of organisms not within the quadrats was noted and abundance estimated.

Figure 1. Locations of anchialine ponds and marine biota monitoring transects off NELHA.

Figure 2. Locations of northern (upper) and southern (lower) anchialine pond groups at NELHA. Figures not to the same scale.

RESULTS

The results of the survey of the anchialine ponds at NELHA performed on November 14, 2010 are presented in Table 1. The distribution and abundance of organisms in the northern and southern pond complexes were very different, but generally similar to the conditions observed in previous surveys (Brock, 1995; Oceanic Institute, 1997; Brock, 2002; Oceanic Institute, 2007; Brock 2008; Ziemann 2008, 2009, 2010), with the exception of apparent changes to several ponds in the northern complex. The northern ponds are shallow and located near the shoreline (Figure 2 upper). Ponds N1 – N4 are formed in depressions in the low-lying lava; Pond N5 is at least partially man-made, consisting of a depression in the back-beach rubble formed by manual removal of rubble material. Pond N5 is closest to the shoreline and separated from the ocean by the rubble back-beach. Pond N6 was recently dug in the sandy back-beach area adjacent to Pond N1. Salinity during the May 2009 survey was uniform in the five northern ponds (10 ppt). Temperature was lowest (18.0 deg C) in pond N1 and elevated (22.0 deg C) in Pond N4.

Data for surveys conducted between 1989 and the present are compiled in Appendix A. In surveys prior to July 2006, ponds N2, N3 and N4 contained growths of the marine grass *Ruppia maritima*, and while this plant is typically used as shelter by the anchialine shrimp *Halocaridina rubra*, no shrimp were seen in the *Ruppia* growths. In July 2006, however, the *Ruppia* had been manually removed from these ponds and replanted in pond N5. Large numbers of *Halocaridina rubra* and *Metabateaus lohena* were seen in the now-barren Ponds N4a and N4b, where they had not been seen in prior surveys. During the January 2007 survey, neither *H. rubra* nor *M. lohena* were seen in any of the northern ponds, a return to conditions observed prior to July 2006.

No crustaceans were observed in the northern ponds in the survey conducted by Brock in December 2007. Notably, all exotic fish were absent in the northern ponds as well. Many of the northern ponds have been characterized by the presence of exotic fishes (*Poecilia* sp.), which exclude the red shrimp, *Halocaridina rubra*. With the removal of exotic fishes from the ponds, native crustaceans returned. *Halocaridina rubra* were observed in all five northern ponds in the August 2008 survey (Brock 2008) and in greater numbers during the October 2008, May 2009 and March 2010 surveys (Ziemann 2008, 2009, 2010). The numbers and distributions of *H. rubra* in the northern ponds in the present survey were very similar to those observed in the previous three surveys. Notably, *H. rubra* were observed for the first time in low densities (10/quadrat) in the recently-dug Pond N6.

Historically, the small snail, *Melania* sp., was common in these ponds, primarily on the sediment covered pond bottoms of Ponds N1, N3 and N4, and less so on the rocky sides. Since the survey conducted by Brock in 2006, however, snails have been notably absent from all of the northern ponds.

The southern ponds are located inland at some distance from the shoreline (Figure 2 lower). Water temperature in the northern group of ponds (S1 – S5) was slightly warmer (19 - 20 deg C) than the southern group (S6 – S9), where temperatures were uniformly 18.5 – 19.0 deg C. Salinity in the southern ponds was slightly lower than in the northern ponds and ranged from 8 - 10 ppt.

Table 1. Physical and biological data collected in anchialine ponds within the NELHA facility in November 2010. Pond locations are given in Figure 2. Surveys were conducted at or near high tide (+1.0 feet).

Pond	Temp (deg C)	Salinity (ppt)	<i>Ruppia maritima</i>	<i>Melania</i>	<i>Assementia</i>	<i>Theodoxus cariosa</i>	<i>Grapus tenuicrusatus</i>	<i>Halocaridina rubra</i>	<i>Metabataeus lohena</i>	<i>Pocilia</i> sp.	other species, comments
N1	18.0	10	+					++	-	-	<i>H. rubra</i> 100-150/quad over sand; 160/quad in gravel along pond edge; 50/quad in <i>Ruppia</i> .
N2	21.0	10						+	-	-	<i>H. rubra</i> 35/quad on rocks; 75/quad on rubble.
N3	20.5	10	++					++	-	-	<i>H. rubra</i> 200/quad on rock shelf; TNTC/quad on <i>Ruppia</i> ; <i>Ruppia</i> covers 80% of central basin
N4	22.0	10			+			+	-	-	<i>H. rubra</i> 15/quad on rocks; 200/quad on sand.
N5	20.0	10	+					++	-	-	<i>H. rubra</i> 150/quad on rock shelf; 125/quad along edge; 50/quad on <i>Ruppia</i> ; <i>Ruppia</i> covers 20% of central basin, evidence of recent removal of <i>Ruppia</i> .
N6	20.0	10									Man-made pond; <i>H. rubra</i> 10/quad on sand bottom.
S1	20.0	8						-	-	+	Poecilids present, no shrimp
S2	20.0	8						+	+	-	<i>H. rubra</i> 10/quad on rocks.
S3	19.0	9						-	-	+	Poecilids present, no shrimp
S4	19.0	10						+	-	-	<i>H. rubra</i> 15/quad on rocks.
S5	20.0	10						-	-	+	Poecilids present, no shrimp
S6	18.5	9						++	-	-	<i>H. rubra</i> 50/quad on rocks.
S7	18.5	9						-	-	++	Poecilids present, no shrimp.
S8	19.0	9						++	+	-	<i>H. rubra</i> 25/quad on rocks; 2 <i>M. lohena</i> ; 1 dead <i>M. grandis</i>
S9	18.5	8						++	+	-	Beach heliotrope previously covering pond now cut back. <i>H. rubra</i> 30/quad on rocks; 1 <i>M. lohena</i> .
Qualitative abundance:											
			-								none observed
			+								few animals; scattered plants
			++								animals common; plants abundant in patches
			+++								animals too numerous to count; plants covering substrate

The first exotic fishes in the southern ponds were recorded in the May 2002 survey (Brock, 2002) in Pond S7. Subsequently, exotic fishes expanded to all the southern ponds (except S6 and S9, which are dry at low tide) by January 2007. As a result, no anchialine pond crustaceans were observed in surveys conducted in December 2007 and August 2008 (Brock 2008). During the October 2008, May 2009 and March 2010 surveys (Ziemann 2008, 2009, 2010) and the present survey, however, exotic fishes were observed in four ponds (S1, S3, S5 and S7). *Halocaridina rubra* were present in the ponds which did not contain exotic fish. Another common pond crustacean, *Metabateaus lohena*, was seen in Pond S8, a deeper pond previously overgrown with beach heliotrope, but which had been cleared of overgrowth between October 2008 and May 2009, and in Pond S9, a thin fissure in the barren lava that is dry at low tide.

DISCUSSION

On the island of Hawaii, anchialine ponds are found along the west and south coasts. Studies of the ecology of these unique communities have established that the populations are generally hardy and apparently unaffected by nearby terrestrial activities, including the development of residences, hotels and golf courses. The major impact to the anchialine pond communities has been the inadvertent or purposeful introduction of exotic fishes into the ponds. From 1972 to 1985, exotic fish spread from 15% to 46% of the ponds along the Kona coast (Brock, 1985; Bailey-Brock and Brock, 1993); recent estimates suggest that over 90% of the ponds are now infested (Brock, unpublished data). With the introduction of exotic fishes comes the decline or complete absence of the ubiquitous small red shrimp (*Halocaridina rubra* or opae ula). These shrimp constantly graze on the microalgae which grow in the brightly-lit, high nutrient ponds. With the removal of the shrimp, ponds often become overgrown with mats of filamentous algae.

The ponds at NELHA exhibit both groups of ponds with high abundance of *H. rubra*, and others where *H. rubra* is excluded by the presence of exotic fishes. Attempts to eradicate the exotic fish in the northern ponds appear to have been successful, as they have not been observed in these ponds since 2007.

For several years, exotic fish were present in most of the northern ponds and one-third of the southern ponds. During surveys conducted from December 2007 to the present, however, exotic fishes were not observed in any of the northern ponds and only three of the southern ponds, the decrease presumably the result of eradication efforts. Concurrently, the ponds without exotic fish all contained populations of the common red shrimp *Halocaridina rubra*.

None of the anchialine ponds on the NELHA site exhibit any conditions which might be attributable to anthropogenic inputs of material to the ponds. Water clarity remains high, and macroalgal growth is minimal even in ponds containing exotic fish. A large pond dug in the sandy back-shore sometime in late 2008 or early 2009 now, two years after being dug, contains significant numbers of *Halocaridina rubra*. There is no evidence of any long term changes attributable to operational activities of NELHA on the anchialine ponds at NELHA.

NELHA BENTHIC MARINE BIOTA MONITORING PROGRAM

November 2010

INTRODUCTION

Benthic communities are considered to be the potentially most useful and sensitive indicators of the environmental impact of terrestrial activities because the components of these communities are fixed in place and cannot move from an area undergoing impact; thus their exposure to potentially harmful materials has components of both concentration and duration. Changes in coral community abundance or diversity may result from changes in the quantity or quality of groundwater discharged along the coastline. In the Hawaiian Islands, the structure of coral communities is also a response to the periodic physical impacts of storm- or hurricane-generated waves (Dollar, 1975, 1982; Dollar and Tribble, 1993).

Between 1991 and the present, 33 surveys of the benthic communities have been completed. The results of surveys between 1991 and 1995 are summarized in Marine Research Consultants, 1995; for surveys between 1995 and 1997 in Oceanic Institute 1997; for surveys performed from 1997 to 2002 in Marine Research Consultants, 2002; for surveys from July 2005 to January 2007 in Oceanic Institute 2007; for October 2007 and July 2008 surveys in Marine Research Consultants 2008; and for the October 2008, May 2009 and March 2010 surveys in Ziemann 2008, 2009, 2010. Results of the survey conducted in November 2010 are reported here.

METHODS

A survey to examine the nearshore benthic marine biota was performed using SCUBA between November 10 - 13, 2010. Surveys were performed at six locations along the NELHA coastline (Figure 3): Ho'ona Bay, the NPPE site, 12" Pipe - North, 12" Pipe - South, 18" Pipe, and Wawaloli. At each location, a series of three transects was laid out. Transects were performed in the shallow (~5m) boulder zone, the intermediate depth (~8-10 m) reef bench, and the deeper (15-20 m) reef slope. These station locations and transect depths have been chosen as representative of major biotopes along the Kona coast (Dollar, 1975, 1982; Dollar and Tribble, 1993), and are the same locations visited in previous surveys (Marine Research Consultants, 2008; Brock, 2008; Ziemann, 2008). At each location, a 50 m transect line was laid out parallel to the depth contours. At ten randomly selected points along the transect line, photographs of a 0.6 x 1.0 m quadrat frame were taken using a digital camera with a wide angle lens in an underwater housing with a dome port. Lighting was provided by underwater strobes or natural light. Digital quadrat photos were analyzed using Coral Point Count with Excel extensions (CPCe v3.6; National Coral Reef Institute, Nova Southeastern University, 2006). On the computer screen, each digital photo was overlaid with a 20 (vertical) x 10 (horizontal) grid of equally spaced points, and the biotic components and substrate type under each point was recorded. Point count data were exported into Excel spreadsheets for compilation and analysis. For each transect, the mean abundance (as percent cover) of coral species and substrate type was tabulated, and the species diversity (Shannon-Weaver Index) of the coral community (Shannon and Weaver, 1949; Pielou, 1969) calculated.

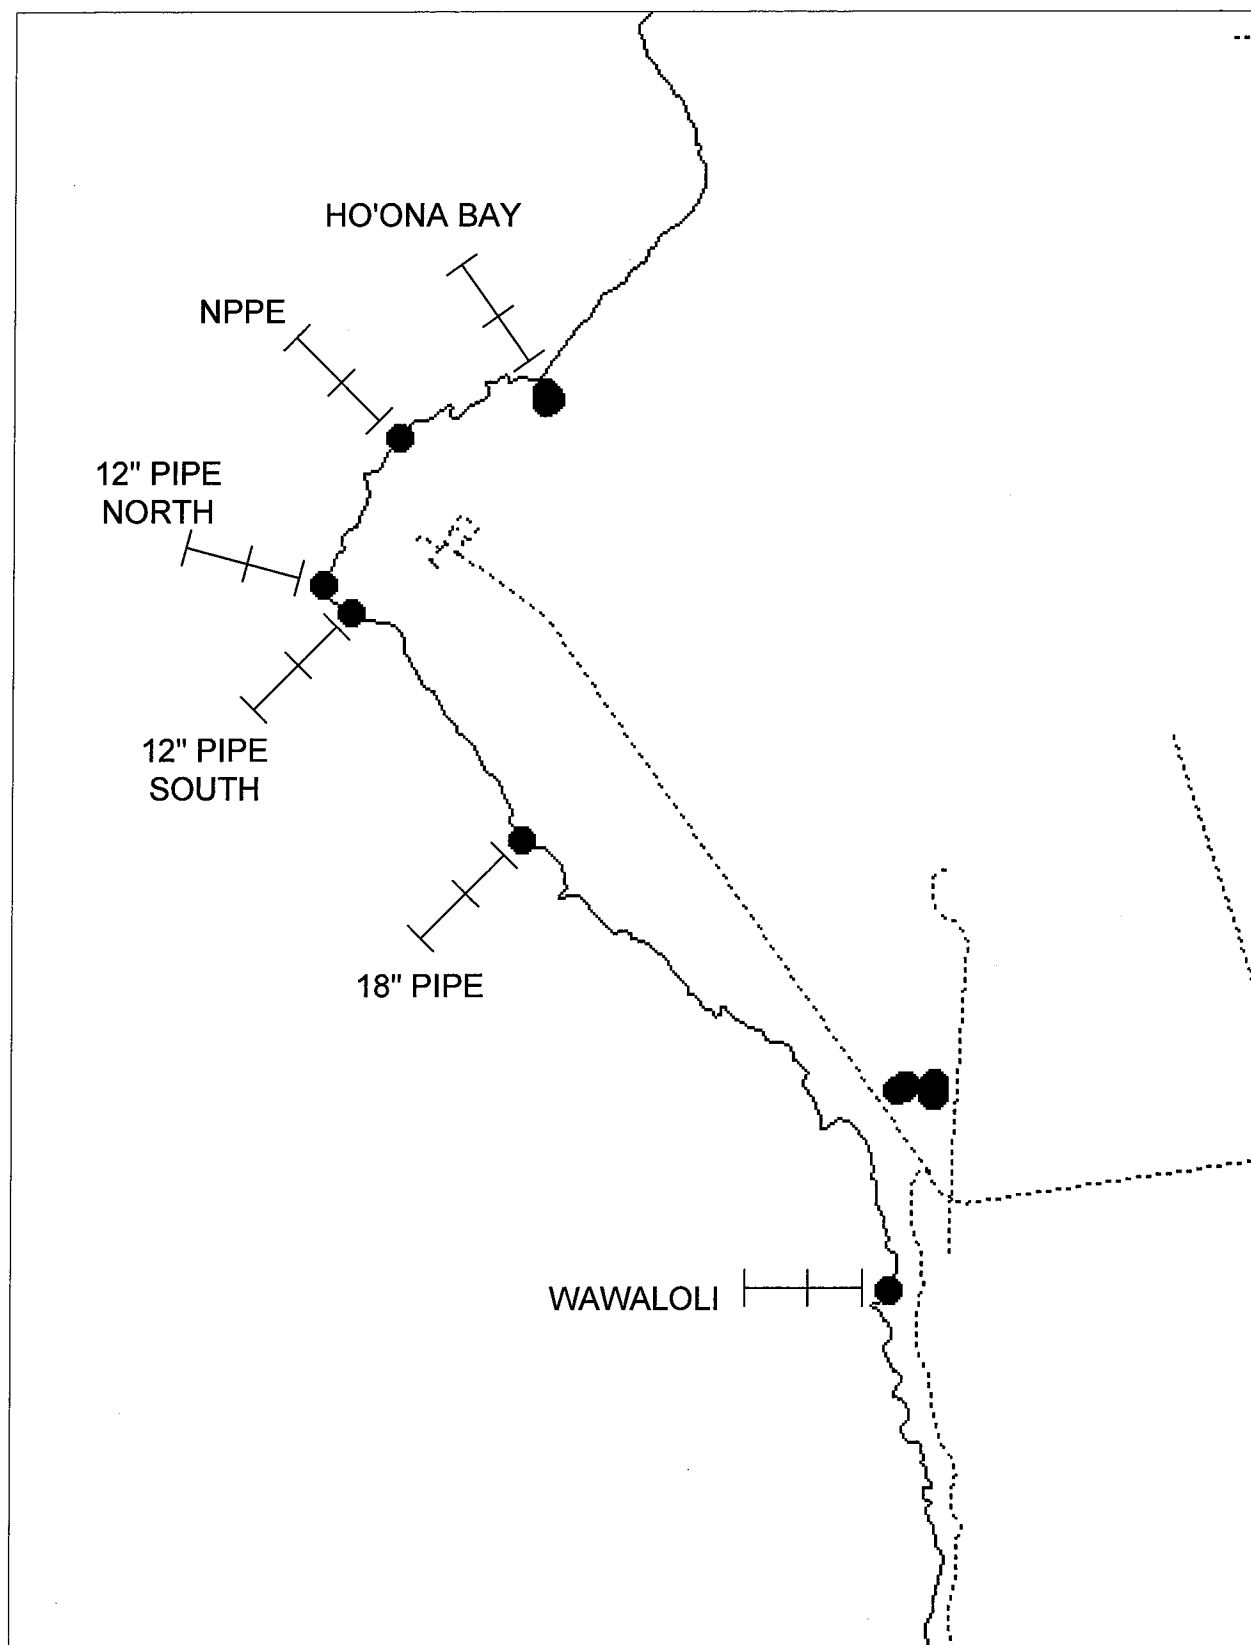

Figure 3. Locations of marine biota monitoring survey transects.

RESULTS

Coral species abundance and coral diversity for the November 2010 survey off NELHA are presented in detail in Appendix B and summarized in Table 2. Color prints of digital quadrat photos are presented in Appendix E. Overall, total coral cover was 46.4%. Two species, *Porites lobata* and *Pocillopora meandrina*, comprised the majority of the coral observed, constituting over 30.5% and 8.7%, respectively. *Porites lobata* and *Pocillopora meandrina* were found throughout all stations and habitat types. *Porites compressa* was abundant (16.8% - 20.0%) only at the deepest reef slope transects at stations NPPE and Ho'ona Bay, the two most northern stations. *Montipora capitata* [previously *verrucosa*], was found at all stations with coverage ranging from 0.6 - 9.3%. Other stony coral species (*Porites monticulosa*, *Pocillopora eydouxi*, *Montipora patula*, *M. incrassata*, *Pavona varians*, *Leptastrea purpurea*) made up generally less than 2% of the benthic cover.

The percent cover of all coral species (Total Coral) in the three habitat types and the individual distribution of the three dominant coral species, *Porites lobata*, *P. compressa*, and *Pocillopora meandrina*, are presented in Table 2. There were differences in coral abundance both between habitat types and also between sites, but only the differences between sites for *P. compressa* were statistically significant ($p = 0.03$, two-way ANOVA; Holm-Sladek pair-wise comparison test). Total coral cover was highest at the NPPE site (60.2%) and ranged from 36.2% to 48.1% at the other sites. Total coral cover in the deep reef slope habitat was higher (51.1%) than the middle (47.1%) or shallow reef habitat (41.0%), but the differences were not statistically significant ($p = 0.34$, two-way ANOVA; Holm-Sladek pair-wise comparison test). Among the deep reef slope stations, total coral abundance was highest at NPPE (75.2%), 12" Pipe North (62.1%) and Ho'ona Bay (59.6%) sites. At Ho'ona Bay and NPPE, this was due to the high abundance of *Porites compressa* (16.8% - 20.0% cover). At the other four deep reef slope stations, *P. lobata* and *Pocillopora meandrina* accounted for the high coral abundance (combined average cover of 34.7% - 37.4%).

Between areas, the highest mean and also maximum coral was found in two most northern areas, the NPPE and 12" Pipe North sites. The most southern area, Wawaloli had the lowest overall coral coverage. The highest mean *Porites lobata* coverage was found at the NPPE site (51.7%), with similar but lower coverage at the Ho'ona Bay, 18" Pipe, 12" Pipe North and Wawaloli; lowest *P. lobata* cover was observed at the 12" Pipe South site. For *Pocillopora meandrina*, the 18" Pipe, 12" Pipe North and South stations had the highest mean abundance of all the stations. The differences between these sites were not statistically different ($p < 0.26$).

The number of coral species observed in photoquadrats was not significantly different between sites ($p = 0.68$) or between habitats ($p = 0.14$; two-way ANOVA; Holm-Sladek pair-wise comparison test). The mean number of species observed was highest at Ho'ona Bay (5.3) and lowest at NPPE (4.3). The mean number of species observed at the deep habitats (5.3) was not significantly greater than at the shallow (4.3) or middle (5.2) habitats ($p = 0.14$; two-way ANOVA; Holm-Sladek pair-wise comparison test).

Table 2. Summary of quantitative coral photoquadrat surveys conducted off Natural Energy Laboratory of Hawaii on November 10–13, 2010. Locations of transects are shown in Figure 3. Quantitative data are presented in Appendix B.

Other Benthic Invertebrates

Results of the benthic invertebrate surveys are presented in Appendix C. The primary benthic invertebrates, other than corals, were echinoderms (sea urchins). The most visible invertebrate and most abundant echinoderm species was *E. mathaei*, found at all stations, with highest abundance in the shallow boulder zone and in the intermediate reef bench areas. The other urchin species occurred infrequently throughout the three different habitat zones. *Diadema paucispinum*, *Echinothrix diadema* and *Tripneustes gratilla* were generally observed most frequently in the deeper reef bench and reef slope areas.

Comparative Analysis - Benthic Marine Resources

Data for the NELHA benthic marine resources monitoring program has been collected since May 1989. However, the current arrangement of six stations with three transects at each station was not established until May 1992. Since that time, 33 surveys have been conducted. The balanced design and complete coverage afforded by the current survey arrangement provides a powerful database for statistical analysis. Although the three surveys performed between May 1989 and March 1992 provide additional temporal scale, their incomplete coverage provides little statistical power. Therefore, the statistical analyses which follow incorporate data only from May 1992 to November 2010, inclusive.

The surveys for benthic marine resources provided data for a number of variables (total coral cover, and cover for two dominant coral species per transect) for three sources of variance (date, location [stations] and habitat [transects]). Three-way analysis of variance (ANOVA) tests were performed on three sources of variance (date x location x habitat) for 33 surveys from May 1992 to November 2010 for total coral cover, *Porites lobata* abundance and *Pocillopora meandrina* abundance using SigmaStat for Windows, a PC-based statistical analysis program. However, all data sets failed the test of normality, in raw form or after transformations (log, exp, arc-sine). Therefore, one-way ANOVA tests utilizing ranked data (Kruskal-Wallis analysis of variance on ranks) were conducted on each factor independently; pair-wise comparison comparisons on ranked data using the Tukey test were performed to identify significant differences between all pairs. The level of significance for all tests was $p = 0.05$.

Results of the one-way K-S analysis of variance (ANOVA) on ranks for total coral cover, *Porites lobata* abundance and *Pocillopora meandrina* abundance are summarized below and presented in detail in Tables 3 – 5, respectively. Mean total coral, *P. lobata* and *Poc. meandrina* cover were all significantly different for date, location and habitat.

Summary of three-way analysis of variance on ranked data (Kruskal-Wallis test) for quantitative benthic community abundance for the period May 1992 – November 2010.

TEST	Source of Variance	Probability	Significance
Total coral cover	Date	<0.001	highly significant
	Location	<0.001	highly significant
	Habitat	<0.001	highly significant
<i>Porites lobata</i> abundance	Date	<0.001	highly significant
	Location	<0.001	highly significant
	Habitat	<0.001	highly significant
<i>Pocillopora meandrina</i> abundance	Date	<0.001	highly significant
	Location	<0.001	highly significant
	Habitat	<0.001	highly significant

The mean total coral cover for each date, location and habitat and the results of the pair-wise comparisons (Tukey tests) from the one-way ANOVA on ranks are presented in Table 3. Total coral abundance showed a clear pattern over time. Mean total coral abundance did not change significantly from May 1992 through May 1997, although there was a generally increasing trend, with values ranging from 16.9 to 27.0%. Mean cover almost doubled, from 27% to 42.5%, between surveys conducted in May 1997 and November 1997. Mean total coral cover remained high (40.7% to 52.5%) through June 2002. In July and November 2005, after a nearly three-year hiatus in monitoring, the mean total coral cover was 30.8 and 30.2%, respectively, significantly higher than during the May 1992 to May 1997 period, but significantly lower than during the November 1997 – June 2002 period. Mean coral cover was reported as 52.4% and 54.7% for surveys in October 2007 and July 2008. Mean total coral cover was 39.5% in the survey conducted in October 2008, 39.5% in May 2009 and 43.2% in March 2010 and 46.4% in the present survey.

Mean total coral cover was significantly different between all sites except the 12" Pipe North, 12" Pipe South and 18" Pipe sites. Mean total coral cover was highest (52.3%) at the NPPE site, decreasing through the Ho'ona Bay, 12" Pipe S and N, and 18" Pipe sites to a minimum of 22.0% at the Wawaloli site. Mean total coral cover was significantly different between the deep reef slope (42.0%), the reef bench (37.0%), and the shallow boulder (26.7%) stations.

The mean *P. lobata* cover for each date, location and habitat and the results of the pair-wise comparisons (Tukey tests) from the one-way ANOVA on ranks are presented in Table 4. In general, the patterns of *P. lobata* distribution were similar to the patterns for total coral cover. *Porites lobata* cover was low and similar between May 1992 and May 1997, ranging from 10.0 to 14.6%. *Porites lobata* cover increased between surveys conducted in May 1997 and November 1997 from 13.7% to 20.6%, values that were significantly different. *Porites lobata* cover remained high and not statistically different from November 1997 through the present survey, ranging from 16.7 – 30.7%.

As for total coral cover, *P. lobata* cover was highest at the NPPE station (31.4%) and lowest at Wawaloli (13.8%) and the 18" Pipe (12.8%) sites, and increased from lowest values (13.5%) in the shallow boulder habitat to highest values (22.6%) in the deep reef slope habitat.

The mean *Pocillopora meandrina* cover for each date, location and habitat and the results of the pair-wise comparisons (Tukey tests) from the one-way ANOVA on ranks are presented in Table 5. In general, the patterns of *Poc. meandrina* distribution were similar to the patterns for total coral cover. *Poc. meandrina* cover was low and similar between May 1992 and December 1996, ranging from 3.7 to 6.3%. Mean *Poc. meandrina* cover increased between surveys conducted in May 1997 and November 1997 from 8.0% to 13.0%, values that were significantly different. *Pocillopora meandrina* cover increased between surveys conducted in December 1996 and November 1997 from 6.3% to 13.0%, values that were significantly different. *Pocillopora meandrina* cover remained high and not statistically different from November 1997 through the present survey, ranging from 8.1 – 20.3%.

Mean *Poc. meandrina* cover was similar (12.0 – 13.5%) at the NPPE, 18" Pipe, and 12" Pipe South sites. The 12" Pipe North, Wawaloli and Ho'ona Bay sites showed significantly lower cover (3.8 – 5.4%). Mean *Poc. meandrina* cover was similar at the shallow boulder (10.1%) and middle reef shelf (11.3%) sites, and significantly lower at the deep reef slope (7.6%).

DISCUSSION

The distributions of the predominant coral species appear to define particular biotopes which fit the general descriptions (Dollar, 1975, 1982; Dollar and Tribble, 1993) of typical coral zonation: the area of high energy where *Porites lobata* and *Pocillopora meandrina* dominated; the intermediate bench zone where *P. lobata* was more abundant than *Poc. meandrina*; and the deeper reef slope zone dominated by *P. compressa*. The distribution of these biotopes along the NELHA coastline was not uniform, however, and the location of the survey transects is not uniform within these zones. For example, only the deepest transects at Ho'ona Bay and the NPPE station actually covered the deep *P. compressa* zone; all other deep transects were more shallow and located within the reef bench zone where *P. lobata* dominated or the shallow boulder zone where *P. lobata* and *Poc. meandrina* dominated.

Overall total coral cover and *Porites lobata* abundance showed the same general patterns of distribution, increasing in abundance from south to north along the NELHA coastline, and increasing in abundance from shallow to deep.

Pocillopora meandrina was dominant in the boulder zone along part of the coastline, but was found in low abundance in the boulder zone at the northern-most and southern-most stations. The low abundance of *Poc. meandrina* at these stations is likely due to the decreased wave action experienced there, a result of the orientation and bathymetry, which appears to provide some level of shelter from predominant storm waves.

Table 3. Summary of one-way analysis of variance (ANOVA) of total coral abundance (percent cover) for surveys conducted off NELHA from 1992 - 2010. For each ANOVA factor (date, location and biotope), data which are not significantly different (Tukey test) are grouped by letter.

All three coral variables (total coral cover, *Porites lobata* abundance and *Pocillopora meandrina* abundance) showed the same temporal pattern: levels that were statistically similar between May 1992 and May 1997, with some suggestion of small increases over that period; a sudden increase on the order of 60 - 100% between the May 1997 and November 1997 surveys; relatively similar levels between November 1997 and May 2002; decreases in the July 2005 – January 2007 surveys to levels slightly higher but not statistically significantly different from those observed in May 1997; increases to the highest levels observed in surveys conducted in October 2007 and July 2008 and decreases in October 2008 to levels similar to January 2007. Increases in coral cover, whether for individual species or for total coral, on the order of 60 – 100% over a 6-month period are likely not reflections of actual increase in coral abundance; rather, they may represent basic changes in the manner or area in which surveys were conducted.

Benthic monitoring surveys have been conducted by different parties over the course of the CEMP program: Marine Research Consultants (MRC, Dr. Steven Dollar) from August 1991 – May 1995; Oceanic Institute (OI, Dr. David Ziemann), four surveys from November 1995 – May 1997; Marine Research Consultants (MRC, Dr. Steven Dollar), ten surveys from November 1997 – June 2002; Oceanic Institute (OI, Dr. David Ziemann), four surveys between July 2005 and January 2007; Marine Research Consultants (MRC, Dr. Steven Dollar), two surveys in October 2007 and July 2008; and Dr. David Ziemann, the surveys in October 2008, May 2009 March 2010 and November 2010. In their report (Marine Research Consultants, 1998) of the results of the November 1997 survey, the first conducted by MRC following the two-year period during which surveys were conducted by OI, the MRC authors chose not to include the data from the OI surveys of November 1995 – May 1997 in their analysis, speculating “it appears that locations of the monitoring sites were not identical between the two investigators”, but the present analysis shows the results of the four OI surveys between November 1995 and May 1997 were not significantly different from those conducted by MRC up to May 1995. Table 6 of the MRC report for the November 1997 survey (Marine Research Consultants, 1998) clearly shows highly significant differences between the coral abundances found in their prior surveys (through 1995) and their November 1997 survey. While the significant difference between surveys conducted up to May 1995 and after November 1997 is recognized (Marine Research Consultants, 1998), it is attributed to “increased coral cover at many of the survey sites directly off the NELHA facility.”

The overall mean total coral cover, mean *Porites lobata* cover, and mean *Pocillopora meandrina* cover for six periods during which monitoring was conducted by different contractors are presented below. Figures in bold type represent mean values that are significantly different from the remaining means (see Tables 3 – 5 and accompanying text for details). Mean total coral cover and cover for *P. lobata* and *Poc. meandrina* was not significantly different between monitoring conducted by MRC in 1992 – 1995, by OI between 1995 – 1997, by OI in 2005 – 2007 and by Ziemann between 2008 - 2010. Mean values were significantly higher, however, for the monitoring conducted by MRC between 1997 - 2002 and 2007 - 2008.

Dates	Monitor	Mean Total Coral Cover	Mean <i>Porites lobata</i> cover	Mean <i>Pocillopora meandrina</i> cover
May 1992 – May 1995	Marine Research Consultants	20.4	11.7	4.5
Nov 1995 – May 1997	Oceanic Institute	23.4	12.1	6.7
Nov 1997 – Jun 2002	Marine Research Consultants	47.4	21.6	11.2
Jul 2005 - Jan 2007	Oceanic Institute	33.3	19.1	8.8
Oct 2007 – July 2008	Marine Research Consultants	53.6	30.3	11.0
Oct 2008 – November 2010	David A. Ziemann	42.2	27.4	8.2

Mean total coral cover, and cover for *P. lobata* and *Poc. meandrina* increased by 21.8%, 15.7% and 3.7%, respectively, over the approximately 24-year period 1992-1995 and 2010; these equate to rates of increase of 4.45%, 5.59% and 3.43% per year. These rates of increase are consistent with natural increases in coral cover on Hawaiian reefs. These data suggest that there have been no significant changes in coral abundance that might be attributable to operations at NELHA, or to natural disturbances such as storm surf.

NELHA NEARSHORE MARINE FISH RESOURCES MONITORING PROGRAM

November 2010

INTRODUCTION

The fish community at NELHA has long been recognized as being particularly abundant and speciose (Brock, 1985; Brock, 1995). Nearshore fish communities might be expected to respond in a quantifiable way to changes in the natural input of material via groundwater, either directly or in response to changes at lower trophic levels. It is upon this expectation that the CEMP has focused activities on the nearshore fish communities at NELHA. Between 1989 and the present, 33 surveys of the fish communities have been completed. The results of the first 12 surveys through May 1995 are summarized in Brock, 1995; for November 1995 through May 1997 surveys in Oceanic Institute 1997; for surveys conducted between November 1997 and June 2002 in Brock, 2002; for July 2005 – January 2007 in Oceanic Institute 2007; for December 2007 and August 2008 in Brock 2008; for October 2008, May 2009 and March 2010 in Ziemann 2008, 2009, 2010. Results from the current survey performed in November 2010 are presented below. The data from the 33 complete surveys (May 1992 – March 2010) are used in the subsequent analysis of long-term trends.

METHODS

Surveys to examine the nearshore fish populations were performed using SCUBA between November 10-13, 2010. Surveys were performed at six locations along the NELHA coastline (Figure 3, above): Ho'ona Bay, the NPPE site, 12" Pipe - North, 12" Pipe - South, 18" Pipe, and Wawaloli. At each location, a series of three transects were laid out, starting at permanently placed markers or facility features (NELHA supply pipes). Transects were performed in the shallow (~5m) boulder zone, the intermediate depth (~8-10 m) reef bench, and the deeper (15-20 m) reef slope. These station locations and transect depths have been chosen as representative of major biotopes along the Kona coast (Dollar, 1975, 1982; Dollar and Tribble, 1993), and are the same locations occupied in previous surveys (Marine Research Consultants, 1995, 2002, 2008; Brock, 1995, 2002, 2008; Oceanic Institute, 1997, 2007; Ziemann 2008, 2009, 2010). At each location, a 25 m transect was laid out parallel to the depth contours, and all the fish within a 4 m wide corridor, from the bottom to the surface, were identified and counted. The size of each fish was also estimated for calculation of biomass (Maynard, 1988).

The results of the survey were tabulated and basic statistics generated: the total number of species observed, the total number of individuals observed, and the total biomass calculated from species, number of individuals, size of individuals, and tables of weights for representative sizes for each species. Species diversity for fish was calculated using Shannon's Index (Ludwig and Reynolds, 1988).

$$H = - \sum_{i=1}^n \frac{n_i}{n} \ln \frac{n_i}{n}$$

where n_i = the number of individuals in the i^{th} species and n = the total number of individuals on the transect.

RESULTS

The results of the fish surveys conducted off NELHA in March 2010 in terms of number of species, individual abundance, biomass, and species diversity are summarized in Table 6 and Figure 4 and presented in detail in Appendix D.1 – D.5.

Numerical Abundance and Habitat Distribution

The number of individuals per transect for the November 2010 fish survey off NELHA are summarized in Table 6. Numerical abundance varied widely between locations and habitats (Fig. 4A). A large (1,000+) school of 'opelu at the middle transect of the NPPE site caused a spike in both abundance and biomass at that station. Not considering that school, the highest mean number of individuals occurred at the 18" Pipe (384) and 12" Pipe South (315) sites. The number of individuals at the other four locations ranged from 226 to 260. The mean number of fish observed was not significantly different between locations ($p = 0.48$), or between biotope types ($p = 0.44$; two-way ANOVA on raw data, Tukey test on interactions).

Number of Species

The number of species per transect for the November 2010 survey off NELHA is summarized in Table 6 and Figure 4B. The mean number of species observed per transect ranged from 22.3 at NPPE to 32.3 at the 18" Pipe site. The number of species observed at the 18" Pipe, 12" Pipe South and 12" Pipe North locations were not significantly higher than the number observed at the other three locations. ($p = 0.15$; two-way ANOVA on raw data, Tukey test on interactions). The mean number of species per transect ranged from 28.3 in the shallow boulder habitats to 27.2 in the middle reef shelf habitat; the differences were not statistically significant ($p = 0.90$; two-way ANOVA on raw data, Tukey test on interactions).

In all areas and habitat zones, most of the species were from two families, the pomacentrids (damselfish) and acanthurids (surgefish). The specific composition of these families varied somewhat between the habitat zones. Seven species were widely distributed throughout all three habitat zones: *Chromis vanderbilti*, *Acanthurus nigrofasciatus*, *Ctenochaetus strigosus*, *Zebrasoma flavescens*, *Paracirrhites arcatus*, *Thalassoma duperrey* and *Chaetodon multicinctus*. Many of these species were usually found dispersed throughout the area, although *Chromis vanderbilti* and *Zebrasoma flavescens* often congregated in schools. *C. vanderbilti* was ubiquitous at all stations except the deep slope habitat at Ho'ona Bay, where it was rare.

Species Diversity

Shannon's Index for species diversity for the March 2010 survey off NELHA is summarized in Table 6. Mean species diversity ranged from 1.70 at the NPPE site to 2.30 at the 12" Pipe South station, but there were no significant differences between locations ($p = 0.19$). Mean species diversity was not significantly different between habitats ($p = 0.11$).

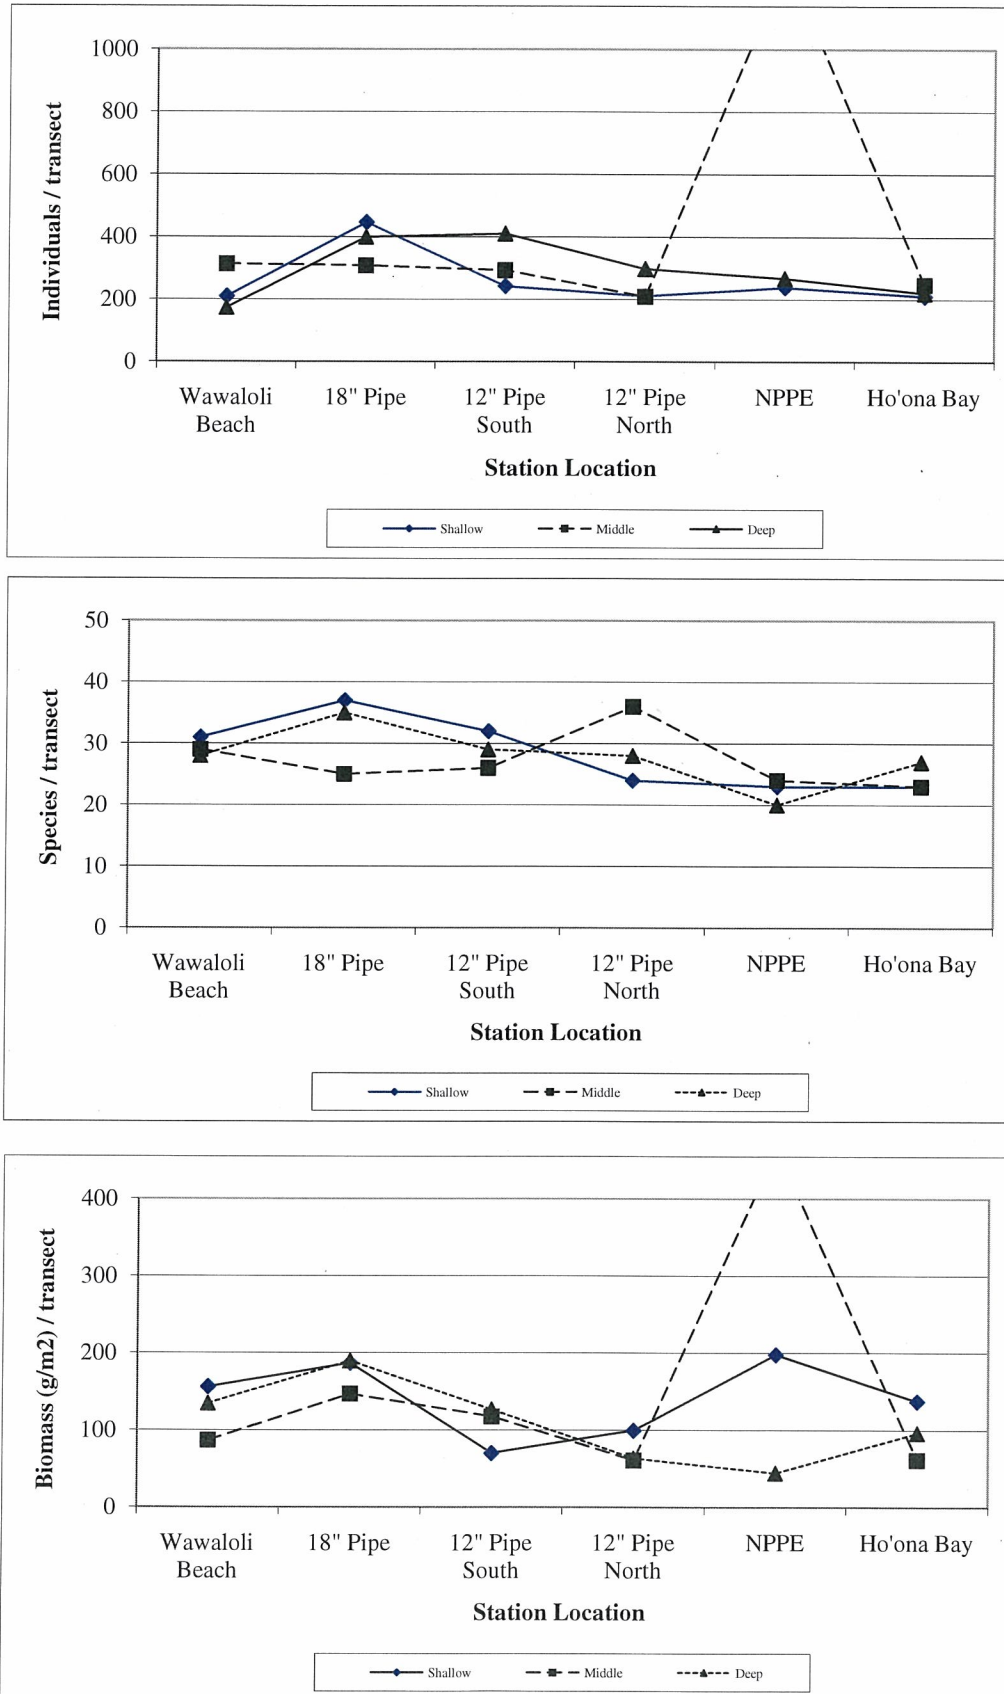

Figure 4. Plots of A: numerical abundance; B: number of species; and C: estimated biomass (g/m²) per transect for fish surveys conducted off NELHA in March 2010. Transect locations are shown in Figure 3.

Biomass

The distribution of fish biomass per transect for the November 2010 survey off NELHA is summarized in Table 6 and presented in Figure 4C. Not including the biomass of the large 'opelu school mentioned above, mean biomass was highest at the 18" Pipe site (174.5 g/m²); differences between other locations were not significant ($p = 0.40$). Mean biomass was lowest in the deep reef habitat (109.1 g/m²) and highest in the shallow boulder (141.3 g/m²) habitat. Differences in biomass between habitats was not significant ($p = 0.70$).

The acanthurid (surgeonfish) family made the largest contribution to biomass because of their large size, schooling tendencies and wide distribution. Pomacentrids (damselfishes), despite their high abundance, contributed only a fraction of the biomass because of their small size (<5 cm).

Comparative Analysis

Data for the NELHA fish monitoring program have been collected since May 1989. However, the current arrangement of six stations with three transects at each station was not established until May 1992. Since that time, 33 surveys, including the present survey, have been conducted. The balanced design and complete coverage afforded by the current survey arrangement provides a powerful database for statistical analysis. Although the three surveys performed between May 1989 and March 1992 provide additional temporal scale, their incomplete coverage provides little statistical power. In addition, the free swimming nature of the fish populations means that they can leave and return to areas of disturbance rapidly, compared to the sessile benthic organisms which are relatively permanently located. Therefore, the statistical analyses which follow incorporate data only from May 1992 to November 2010, inclusive.

The surveys for fish populations provided data for three variables (number of species, number of individuals and biomass per transect) for three sources of variance (date, location [stations] and habitat [transects]). Summary data for these parameters for 33 surveys from May 1992 to May 2009 are presented in Appendix D.3 – D.5, respectively. Three-way analyses of variance (ANOVA) tests were performed on data for each of the three fish population variables using SigmaStat for Windows, a PC-based statistical analysis program. Three-way ANOVA provides an estimate of the significance of the differences between levels for each source of variance, while post hoc pair-wise analyses provides details of which pairs of data are significantly different. If the data failed either the test that the data were normally distributed (normality test) or that the variances were equally distributed, the tests were performed using the rank-transformed data rather than the untransformed data. The ANOVA test utilizing ranked data is known as the Kruskal-Wallis analysis of variance on ranks (K-W test), while the multiple pair-wise comparison test on ranked data is known as the Student-Newman-Keuls Method (SNK test). The level of significance for all tests was $p = 0.05$.

Results of the three-way ANOVA on rank-transformed data for number of individuals per transect, number of species per transect and biomass per transect by date, location and habitat are summarized below and presented in detail in Tables 7 – 9, respectively. Mean number of individuals, species and biomass were all significantly different for date, location and habitat.

Summary of three-way analysis of variance on ranked data (Kruskal-Wallis test) for date of survey, number of individuals, number of fish species and biomass per transect for survey conducted between November 1992 and November 2010.

Biomass	Date	<0.001	highly significant
	Location	<0.001	highly significant
	Habitat	<0.001	highly significant

A summary of the post-hoc S-N-K test for pair-wise comparisons on numbers of individuals per transect for date, location and habitat is presented in Table 7. While the ANOVA indicated significant differences between mean abundance by date, mean abundance showed no temporal pattern of differences that would suggest impacts due to anthropogenic influences (Figure 5). The fifteen surveys with highest abundance levels were significantly higher than the eleven surveys with lowest abundances, but these high levels were separated in time by one to two years, and periods with significantly lower abundances, and are likely due to seasonal variability or the occasional presence of large schools of fish within the transect area. Surveys conducted between May 1992 and November 2010 fell within a group of data that were not significantly different, suggesting that no change in fish abundance has taken place over the 19-year monitoring period.

Mean abundance (Figure 6) was not significantly different at the 18" Pipe (466.6 individuals per transect) and 12" Pipe South (428.3 individuals per transect) sites. Mean abundance at the remaining four locations were not significantly different (303.6 – 324 individuals per transect). Abundance was significantly higher at the deep reef slope habitat (405.1 individuals per transect) than at the other two habitats (330.8 – 334.5 individuals per transect).

A summary of the post-hoc S-N-K test for pair-wise comparisons on numbers of species per transect for date, location and habitat is presented in Table 8. While the ANOVA indicated significant differences between mean number of species by date, mean species per transect showed no pattern of differences that would suggest impacts due to anthropogenic influences (Figure 7). Mean number of species per transect ranged from 24.2 to 33.2, and data for surveys conducted between May 1992 and November 2010 fell within a group of data that were not significantly different, suggesting that no change in the number of fish species in the NELHA area has taken place over the 19-year monitoring period. Mean species per transect (Figure 8) were similar and significantly higher at the 18" Pipe site (32.2 species per transect) and 12" Pipe

South site (30.8 species per transect). The fewest species were seen at the Wawaloli site (23.3 species per transect). Significantly more species were seen in the reef slope habitat (28.9 species per transect) than in the reef bench habitat (27.5 species per transect) or the shallow boulder habitat (28.0 species per transect).

A summary of the post-hoc S-N-K test for pair-wise comparisons on mean biomass per transect for date, location and habitat is presented in Table 9. While the ANOVA indicated significant differences between mean biomass by date, mean biomass showed no pattern of differences that would suggest impacts due to anthropogenic influences (Figure 9). A single survey in November 1998 (Figure 10) had biomass levels higher than the remaining 26 surveys, but this high level is likely due to the presence of large schools of fish within the transect area. Biomass for surveys conducted between May 1992 and November 2010 fell within a group of data that were not significantly different (ranging from 120 – 620 g/m²), suggesting that no change in fish biomass has taken place over the 18-year monitoring period. Mean biomass (Figure 10) was significantly highest at the 12" Pipe South site (287.9 g/m²). Biomass at the 18" Pipe, 12" Pipe North and NPPE sites were lower and not significantly different (175.4 – 232.1 g/m²). Biomass at Wawaloli and Ho'ona Bay were lowest (141.5 – 156.9 g/m²). Biomass was significantly higher at the shallow boulder habitat (244.9 g/m²) than at the other two habitats (166.6 – 202.1 g/m²).

Table 7. Summary of three-way analysis of variance (ANOVA) of number of individuals per transect for surveys conducted off NELHA from 1992 - 2010. All pair-wise comparisons tested by Holm-Sidak method. For each ANOVA factor (date, location and biotope), data which are not significantly different are grouped by letter.

NELHA Biota Monitoring Summary Data

Figure 9. Plot of mean (standard deviation) biomass per transect for each survey off the NELHA site from 1992 through 2010.
Error bars +/- one standard deviation of the mean.

NELHA Biota Monitoring
Summary Data

Figure 10. Plot of the estimated biomass (g/m²) on transects across the three biotopes at each of six survey locations off NELHA between 1989 and 2010.

DISCUSSION

In all areas and habitat zones, most of the fish species observed during the monitoring surveys off NELHA were from two families, the pomacentrids (damselfish) and acanthurids (surgeonfish). The composition of the species within these families varied slightly between the habitat zones. In contrast, several species were found only within one of the three habitat types. The distributions of these two groups of fish reflect, in the first group, their ability to utilize a wide range of habitat types and resources, while in the second group, the fact that their habitat requirements are much narrower. It is likely that environmental impacts would not be reflected in changes in the first group, since they are able to utilize a wide range of habitat and could easily move away from a source of disturbance. Species located only in the boulder zone, however, would seem to be limited in their capacity to move to other habitats and might therefore be more subject to influence from terrestrial activities.

Throughout the survey area, schools of fish, mainly opelu (*Decapterus macarellus*), *Acanthurus blochii*, *A. olivaceus*, and *Naso literatus* roamed between the habitat zones, especially between the reef bench and slope zones. These schools can have a dramatic impact on the abundance and biomass calculations when they pass through the transect area (e.g., in December 1997 when a spawning aggregation of surgeonfish [pualu, *Acanthurus mata* or *xanthopterus*] which passed over the shallow transect at the 12" Pipe South station comprised 81% of the biomass for that transect [Brock, 2002]). In this survey, a school of 'opelu numbering more than 1,000 passed through the transect area of the reef bench at the NPPE site. In addition, we observed that the fish communities in the opposite direction from the transect direction (e.g., to the south, where our transect ran to the north) were often visually different, in terms of species abundance and diversity. These factors illustrate the highly variable nature of the fish communities over very small time and space scales, and imply that any conclusions of change in fish community abundance or distribution needs to be examined carefully in the context of natural variability.

In general, the fish community appears to be most well developed (in terms of number of species, abundance and biomass) in the area from Keahole Point south to the location of the 18" Pipe. The fish community appears to be least well developed off Wawaloli.

The fish community in the NELHA region has remained relatively constant over a period of nineteen years and through several significant storm events. Analysis of variance of number of individuals, number of species and biomass per transect showed no significant changes with time. There is no evidence that the NELHA operations have resulted in any significant changes to the fish communities in the region.
